(2015): Net outcome of competition and facilitation in a wet meadow changes with plant's life stage and community productivity. – Preslia 87: 347–361.

Electronic Appendix 1. – Detailed description of differences in vegetation among plots according to the long-term treatment combinations.

Materials and methods

The transplanting took place in 2000, six years after the start of the long-term management experiment on the site; the plots already differed according to the treatment applied. As the experiment was regularly monitored, we have used two types of data available to characterize the differences among plots in the year 2000: (1) species composition monitored in the central 1x1m square, where presence of all the species of vascular plants and mosses was recorded, and their cover visually estimated; (2) biomass of the central 0.5x0.5m square clipped immediately after finishing the transplant experiment (i.e. early July), where the total dry weight of all vascular plants was measured (notice that biomass data are obviously available for the mown plots only).

Data on the species composition were analyzed using the Redundancy analysis (Šmilauer and Lepš 2014), with log (x+1) transformation of the cover values. The options centering by species with no standardization by samples were applied. All three experimental factors (mowing, fertilization, *Molinia caerulea* removal) were used as explanatory variables. This analysis was accompanied by separate analyses, where each factor was used as the sole explanatory variable, and the other two factors considered as covariables, with the latter analyses providing the amount of variability in species composition explained by each of the factors. Unlike in the previous ordination analyses (Lepš 1999, 2014), *Molinia* was kept in the analyses (unlike in the previous analyses, we are not interested in the effect of *Molinia* removal, but in the extent of differences among plots under various treatments). Canoco 5 software was used for all the analyses (ter Braak & Šmilauer 2012). The data on the total biomass were analysed by the Two-way ANOVA.

Results

The species composition differed among the treatments (Fig. 1) with all the factors had significant effect ($p<0.05$). The explanatory power of fertilization was the highest importance (explaining 21.7% of total variation), followed by mowing (10.7%) and *Molinia* removal (7.6%). The effect of removal was mainly due to presence of *Molinia* in unremoved plots (the proportions of the other species did not change). The fertilized plots were dominated by few competitive tall species, often grasses (*Festuca rubra*, *Holcus lanatus*). Most of the species were confined to unfertilized mown plots, particularly the small species (including our experimental species, *Prunella vulgaris*) and all the mosses.

The biomass in 2000 was nearly twice higher in fertilized than in unfertilized plots, the removal has no effect on the total biomass (which means that the removed species biomass was completely replaced by the other species).

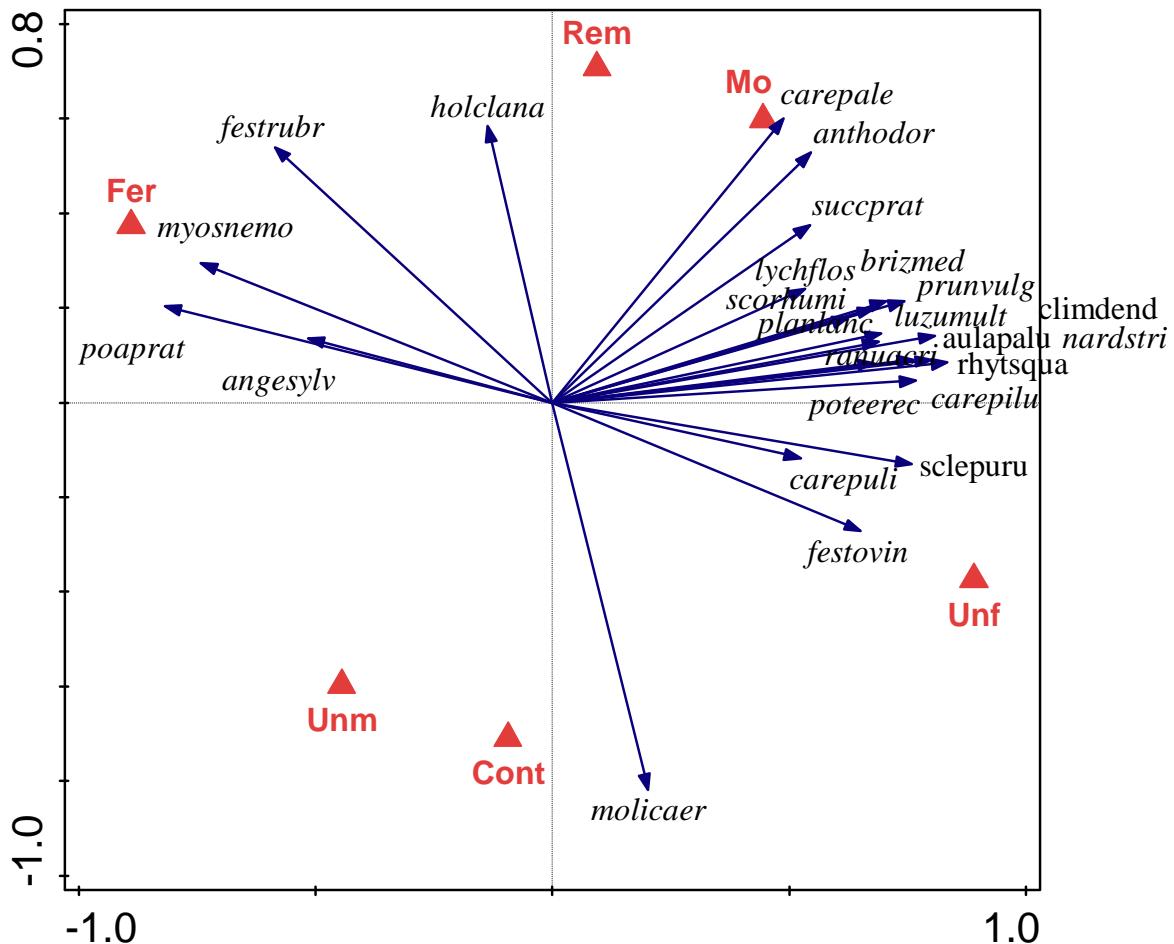

Fig. 1. Results of RDA of species composition in $1 \times 1\text{m}$ plots during the time of experiment in the year 2000. The experimental factors (all significant) are shown as red triangles, and labeled as follows: Unm – unmown, Mo – mown, Unf – unfertilized, Fer – fertilized , Cont – control (unmoved), Rem – removed. The first (horizontal) axis explains 25.2% and the second 9.9% of total variability. Species are shown as arrows, labels of mosses are not in italics. Only the best fitting species are shown. Vascular plants: angesylv – *Angelica sylvestris*, anthodor – *Anthoxanthum odoratum*, brizmed – *Briza media*, carepale – *Carex pallescens*, carepilu – *Carex pilulifera*, carepuli – *Carex pulicaris*, festovin – *Festuca ovina*, festrubr – *Festuca rubra*, holclana – *Holcus lanatus*, luzumult – *Luzula multiflora*, lychflos – *Lychnis flos-cuculi*, molicaer – *Molinia caerulea*, myosnemo – *Myosotis nemorosa*, nardstri – *Nardus stricta*, planlanc – *Plantago lanceolata*, poa_prat – *Poa pratensis*, poteerec – *Potentilla erecta*, prunvulg – *Prunella vulgaris*, ranuacer – *Ranunculus acer*, scorhumi – *Scorzonera humilis*, succprat – *Succisa pratensis*. Mosses: aulapalu – *Aulacomnium palustre*, climdend – *Climatioides dendroides*, rhytsqua – *Rhytidiodelphus squarrosus*, sclepuru – *Scleropodium purum*.

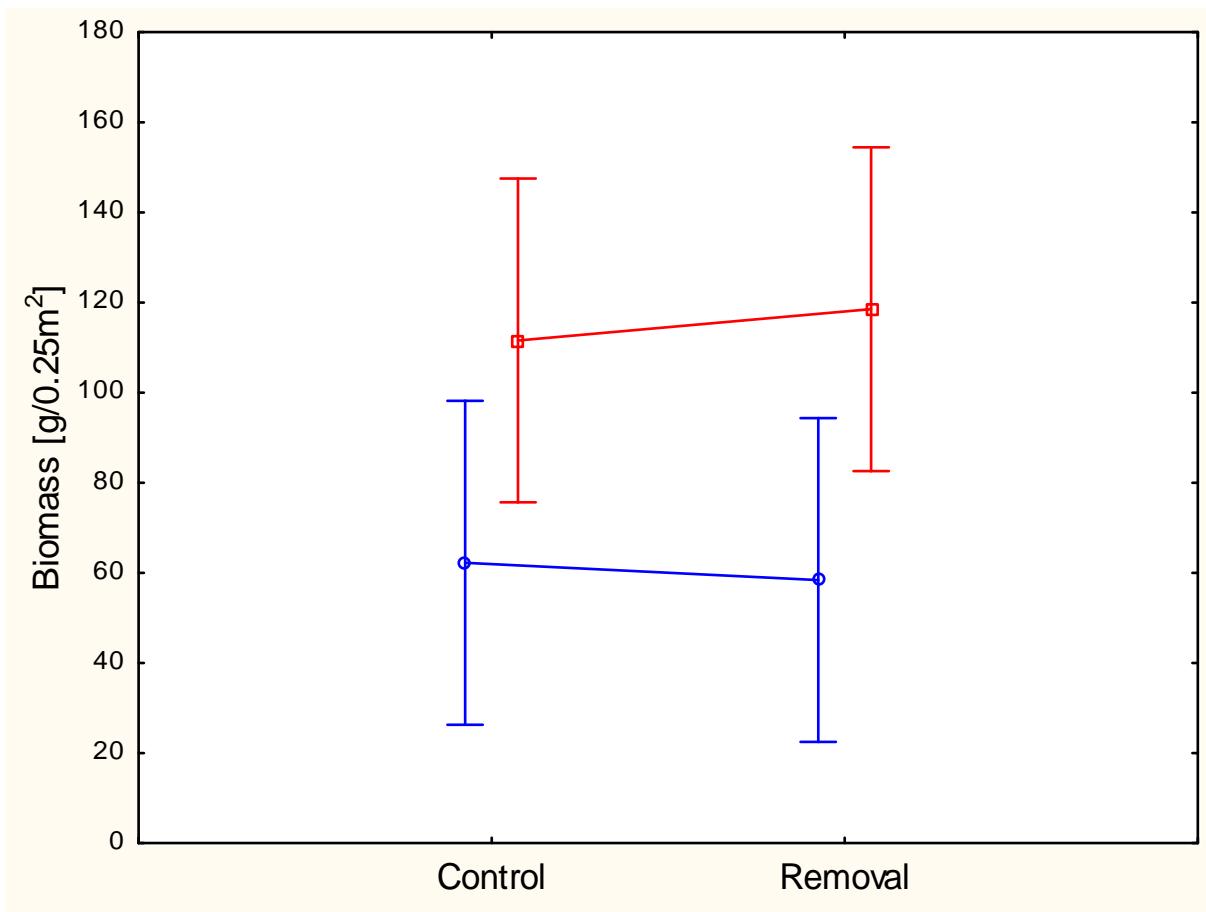

Fig. 2. Above-ground biomass (dry weight per $0.5 \times 0.5\text{m}$ experimental plot) in the mown experimental plots. Fertilized plots are in red, unfertilized in blue. The vertical bars are the confidence intervals. The effect of fertilization is highly significant ($F_{1,8}=12.3$; $p=0.008$), the effect of removal and interaction are non-significant.
